ABSTRACT

Securing communication in networking applications involves many complex tasks that can be daunting even for security experts. The Named Data Networking (NDN) architecture builds data authentication into the narrow waist layer by requiring all applications to sign and authenticate every network-level data packet. To make this authentication usable, the decision about which keys can sign which data and the procedure of signature verification need to be automated. This paper explores the ability of NDN to enable such automation through the use of *trust schemas*. For data consumers, trust schemas provide an automatic way to discover which keys to use to authenticate data packets. For data producers, schemas automate the decision about which keys to use to sign data packets and, if keys are missing, how to create keys while ensuring that they are used only within a narrowly defined scope ("least privilege principle"). We have successfully applied the designed trust schema in several prototype NDN applications with trust models of different complexity, showing the potential of this approach to be generally applicable to a wide range of NDN applications.

Security, Named Data Networking

1. INTRODUCTION

Designing secure systems and network applications usually involves properly authenticating multiple entities in the system and granting these entities with the minimum set of privileges necessary to perform operations. In contrast to traditional IP networks where applications usually rely on an additional layer (e.g., Transport Layer Security [9]) to authenticate connections, Named Data Networking (NDN) [18, 20] is a proposed data-centric Internet architecture that requires every application to name and sign the produced network-level data packets and authenticate received packets. To utilize the data-centric security of NDN without requiring application developers or users to be security experts, system-level support is needed to automate the process of packet signing and authentication.

The power of the NDN architecture comes from naming data hierarchically at the granularity of network-level packets and sealing named data with public key signatures. Producers use key names to indicate which public key a consumer should retrieve to verify signatures of created data packets. Before performing signature verification, consumers can match data and key name to deduce whether the key is authorized to sign the data packet.

To facilitate this matching process, we introduce the concepts of *trust rules* and *trust schemas*. A set of trust rules defines a trust schema that instantiates an overall trust model of an application, i.e., what is (are) legitimate key(s) for each data packet that the application produces or consumes. The fundamental idea is that each trust rule defines a relationship between the name of data and its signing key, e.g., both must share the same prefix, share the same suffix, and/or have specific name components at certain position of the names. Given a trust schema that correctly reflects the trust model of the application, consumers can properly authenticate each retrieved data packet, and data producers can select (and if necessary generate) the right keys to sign the produced data automatically.

In this paper we describe how NDN naming and the use of *trust schemas* enables automation of data signing and authentication in NDN applications with complex trust models. We have implemented a prototype of a trust schema in NDN application development libraries (ndn-cxx and NDN-CCL) and have used it to power the trust management of several NDN applications, including our NDN Forwarding Daemon (NFD), NDN Link State Routing Protocol (NLSR), NDN Domain Name System (NDNS), NDN Repository System (repo-ng), and ChronoChat applications [15].

We organize this paper as follows. Section 2 introduces data authentication in NDN and its threat model. We then explain the value of a trust schema (Section 3), our trust schema design (Section 4), its use in automating trust management (Section 5), and other considerations in their use (Section 6). Finally we review related work and summarize our contribution.

2. DATA AUTHENTICATION IN NDN

NDN fosters a data-centric security model at the network layer [18]: each data packet is uniquely named and this name is bound to the content using a signature. Beside the name, content, signature, and a few other fields, a data packet also contains a `KeyLocator` field [16] to indicate the name of public key to verify the signature, which is simply another piece of named NDN content (Figure 1). Like any other data packet, such packets are also signed, making them equivalent to certificates in NDN [19]. Because NDN names the content carried in a packet, for simplicity, we will use the term "key" to refer to an NDN data packet that carries a public key.

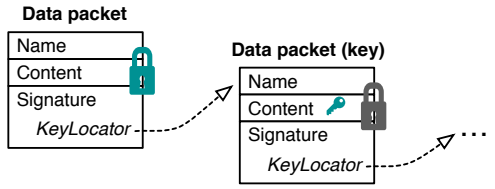

Figure 1: Authentication elements in NDN data packet

In the rest of the paper we assume that given a name, the network can directly retrieve the corresponding data packet. Other considerations, including fetching data packets whose names are not globally routed [1], may require additional steps in data retrieval but will not affect the security model described in this paper.

2.1 Example of Data Authentication

We use a simplified blog website framework as an example throughout the paper to illustrate a possible trust model and our proposed approach to schematize it. The framework includes four groups of entities (Figure 2): the website, website administrators, blog authors, and articles. The website may have a few administrators, who can authorize authors to publish articles on the website. Trust relations between these entities in NDN terms can be captured by signed data packets and chains of keys. When an administrator installs the website software, the installer generates a key[1] to act as the root of trust for the website. The installer process also creates a key for the initial administrator and signs it with the website's key. The initial administrator can

[1]This key may be self-signed or later secured using some trust model, e.g., PKI or Web-of-Trust.

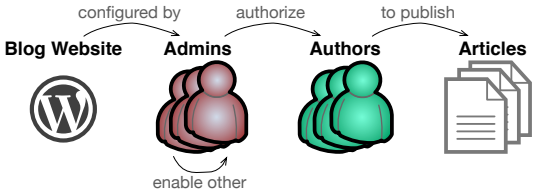

Figure 2: Entities of a simple blog website framework

further delegate management privileges to other administrators by signing their keys, and can add authors into the system by signing the authors' keys. By signing articles using a valid author key, an author can effectively publish its articles on the website.

When a reader retrieves an article, he or she can recursively follow the `KeyLocator` field in each data packet to retrieve the key of the author who wrote the article, the key of the administrator who authorized the author, and the key of the blog website where the article is published. If the reader accepts the website trust model and trusts the public key of the website (or uses PKI or Web-of-Trust mechanisms to verify authenticity of the key), the reader can reliably authenticate legitimate articles through a sequence of data packet signature verifications.

2.2 Threat Model

Threats to data authentication integrity in NDN include failed authentication, mis-authentication, and key compromise. Failed authentication of a legitimate key (false negative) can result in a consumer treating valid data as malicious, potentially leading to denial of service. Mis-authentication of a mis-configured or malicious key (false positive) can cause consumers to accept incorrect or malicious data. These errors can occur when the trust schema (data-key relations) is incorrectly or unclearly defined, or when the authentication mechanism does not fully adhere to the defined schema. A set of commonly used trust schemas written by security experts can not only mitigate these threats, but also facilitate automation of both signing and authentication mechanisms.

When a legitimate key is compromised, an attacker can obtain privileges associated with this key. To mitigate this threat we enforce the "least privilege" principle: each key must have a restricted non-elevating usage scope to limit the damage upon key compromise, and keys with broader privileges should be used only infrequently.

3. WHY WE NEED A TRUST SCHEMA

In general, the relationship between data and key names can be complex. Depending on an application's naming convention and trust model, data authentication may involve a chain of keys (*authentication path*)

across several different namespaces. We use our blog website example introduced in Section 2 to illustrate the necessity of authentication across different namespaces, and highlight the need for the trust schema to concisely express complex trust model relations.

The blog website framework defines entities in the system and also their trust relationships. However, because everything is explicitly named in NDN, the framework also needs to define a naming representation of the entities. Figure 3 shows a possible representation: articles are represented as data packets under the "`/a/blog/article`" namespace, with category, publication year, and unique article identifier; each author obtains a key under the "`/a/blog/author`" namespace with an author identifier,[2] each administrator obtains a key under the "`/a/blog/admin`" namespace with an administrator identifier; and the website itself has a configuration key with the name "`/a/blog`" (e.g., created during the installation of the blog). An implementation of this blog website framework must capture the trust relationship between entities (described in Section 2.1) in terms of the relationship between NDN namespaces. However, this comprehensive naming convention leads to the fact that an authentication path following the trust model has to traverse three namespaces: "`/a/blog/article`", "`/a/blog/author`", and "`/a/blog/admin`" as shown in Figure 3.

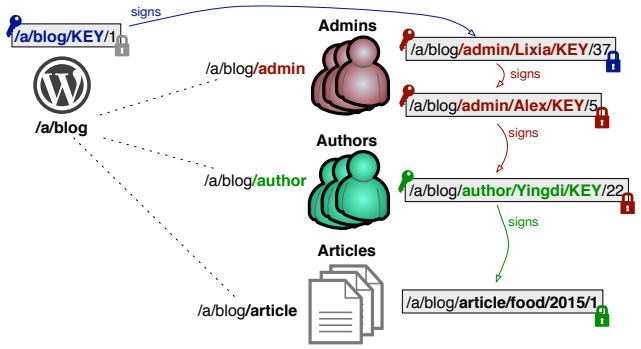

Figure 3: Example of namespaces and authentication paths in a blog website "`/a/blog`"

In theory, it is possible for application developers to hard-code all relationships in the trust model, i.e., relationships between articles and authors keys, between authors and administrators keys, between administrators keys and other administrators keys, and between administrators keys and the configuration key of the website. However, even with a simple trust relationships as in our example, this process can be non-trivial and error-prone. A small implementation error may compromise security of the whole website. For example, a website implementation that accidentally associates authors with author keys rather than with administrator keys may allow authors to authorize another author without the permission from an administrator. Or, an article-publishing application that mistakenly uses an administrator key to sign an article violates the least privilege principle, and may also prevent browsers that comply with the trust model from authenticating articles.

In contrast, when trust relationships are captured by a set of well-defined rules that match data and key names (*trust schema*), a system-level tool interpreting these rules can automatically implement authentication and signing procedures. This ability to automate unburdens developers from individually handling sophisticated data signing and authentication. A trust schema also makes it feasible for security experts to define a set of generalized trust models (e.g., one for all blog websites, one for mail services, etc.) that other applications can reuse. Each reuse can continue to refine and debug the schema, improving it for future applications.

4. TRUST SCHEMA

In this section, we present the trust schema as a tool to define trust models in a generalized way. A trust schema comprises a set of linked trust rules and one or more trust anchors. As we will show later in this section, the trust schema mechanism can be used to automate both authentication and signing processes. To define trust schema rules, we will use a notation similar to regular expressions to express name patterns. Table 1 gives a brief summary of the syntax elements we use in name patterns that are formally defined in [17].

Table 1: Elements of name patterns used in trust schema definitions

`<name>`	Match name component `name`
`<>`	Match any single name component, i.e., wildcard
`<name><>`	Match name component `name` followed by any single name component
`<>*`	Match any sequence of name components
`(...)`	Match pattern inside the brakets and assign it as an indexed sub-pattern
`\n`	Reference to the n-th indexed sub-pattern
`[func]`	Match (for authentication) or specialize (for signing) name component according to function `func` defined pattern, i.e., wildcard specializer
`rule(arg1, ...)`	Derive a more specific name pattern from `rule`'s data name pattern with arguments `arg1`, ...

4.1 Trust Rule

A trust rule is an association of the data name with its corresponding signing key name. There are multiple ways to represent such association. For example, Figure 4(a) shows a simple direct association between an article name and its corresponding author name. This

[2]The last two components of each key name are "`KEY`" and a key identifier. This naming convention allows authors to change keys over time.

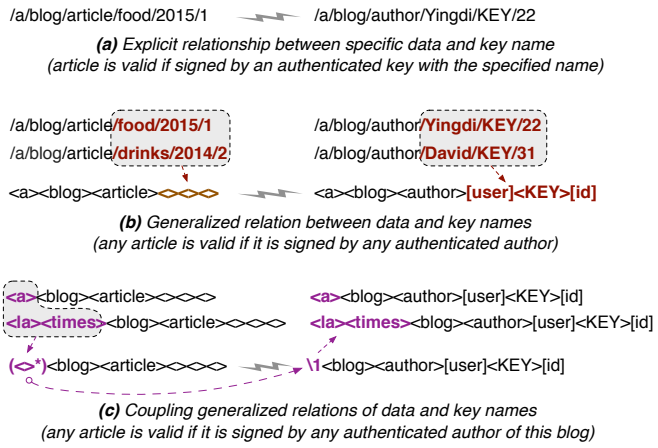

Figure 4: Trust rule generalization

rule precisely captures that the article "`.../food/2015/1`" must be signed by author key "`.../Yingdi/KEY/22`", but says nothing about other articles or authors, even those that share the same naming patterns. If we can generalize the name relationships in trust rules, and reliably link rules to one another, we can construct concise, sophisticated, robust, and re-usable trust models.

4.1.1 Generalizing Trust Rules

A well-defined trust model usually associates the same type of data with the same types of keys, e.g., articles should always be signed by the authors. We can use the naming convention of a given application (or a set of applications that share the same naming convention) to create a set of rules to define the relationships between name patterns for data and keys in that application. This set of trust rules then captures the complete trust model for the application.

In the blog example, all articles share the same prefix "`/a/blog/article`", but each article has its own category, year, and article identifier. One way to generalize this relationship is to use *name patterns* as shown in Figure 4(b). In Figure 4 and later examples, we use the wildcard "`<>`" to match any name component (i.e., the schema does not impose any restrictions on the content of the name component), "`[user]`" to match alphanumerical user identifiers, and "`[id]`" to match numerical key identifiers.

In general, trust models must explicitly associate a data name with its signing key name through matching of name components. In our example, both the article name and the author name must share the same website name ("`/a`"). To capture this constraint, we leverage sub-patterns and repetition syntax, as highlighted in Figure 4(c). We believe this syntax is sufficiently general to capture complex trust model frameworks and to allow reuse by different applications.

4.1.2 Linking Trust Rules

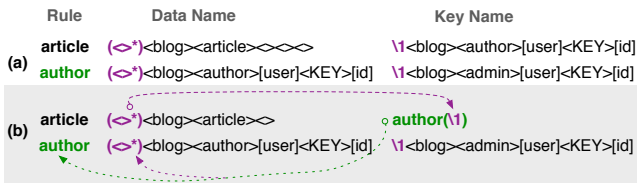

Figure 5: Generalization of trust rule linkage: (a) implicit linkage; (b) explicit linkage

A trust model should also properly associate keys with their signing keys, to ensure that a data consumer can reliably construct chains of keys to authenticate data and that a data producer can correctly choose or initialize its signing keys.

Figure 5(a) defines "`article`" and "`author`" trust rules. The key name pattern in the "`article`" rule will always match the data name pattern of the "`author`" rule, therefore both rules are implicitly linked. However, in order to ensure integrity of the trust model, the schema should deterministically establish an authentication path (or paths) for each authenticated data packet. Therefore, each rule has to be explicitly linked to other rule(s) in the trust schema definition.

To explicitly link rules, we assign each rule a unique identifier to be used in a function-like way as part of the key name pattern, as shown on Figure 5(b). In other words, invoking such rules is similar to invoking a function: invocation substitutes the key name pattern with the data name pattern from the invoked rule, specializing it with the supplied patterns or references to the indexed sub-patterns. In our example, the "`article`" rule invokes the "`author`" rule passing to it the first indexed sub-pattern. For the "`/a/blog/article/food/2015/1`" article, the sub-pattern will expand to "`/a`" and the invocation to the "`author`" rule will return "`<a><blog><author>[user]<KEY>[id]`" name pattern. This linkage imposes the restriction that only authorized authors of blog "`/a/blog`" can sign and publish articles of the blog.

4.2 Trust Anchor

To be complete, a trust schema must also include one or more trust anchors which serve as bootstrapping points for the trust model. A trust anchor is a key that is pre-authenticated using an out-of-bound mechanism, e.g., comes with software packages. In the trust schema we express trust anchors as special rules that include a key name pattern and a pre-authenticated key (e.g., actual key bits or file path). Every successful authentication path must end at a trust anchor. Therefore, a trust schema must always include a way for trust rules to establish the link(s) from data or key names down to trust anchors. Figure 6 shows an example of the trust rule "`admin`" linking to the trust anchor "`root`".

The trust anchor performs two important functions. First, it captures keys that conform to the defined name

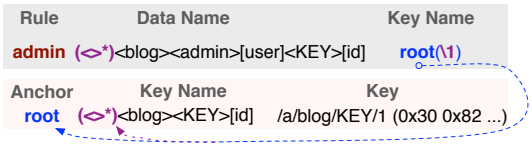

Figure 6: Example of linking trust rule and anchor

pattern, i.e., if a packet is signed with a key that matches the name pattern in a trust anchor, this key must be authenticated using this trust anchor. Second, the anchor ensures that the key name matches exactly the trust anchor's public key and fails to authorize anything else. For example, an administrator's key of another website "`/another/blog/admin/Carl`" will not be a valid administrator's key for "`/a/blog`": the expanded key pattern "`<another><blog><KEY>[id]`" will not match the blog's trust anchor "`/a/blog/KEY/1`". Note that the schema also prohibits another website's admin key to be signed with the blog's trust anchor: the "`admin`" rule will rightfully reject such a key.

4.3 Crypto Requirements

In addition to providing a generalized formal definition of trust rules and trust anchors, a trust schema must also include cryptographic requirements on data signatures, such as hash and signing algorithm, minimum key size. These requirements are not directly related to naming, but prevent consumers from accepting data with easily compromised (weak) signatures. Therefore, a trust schema should clearly state these parameters as an essential part of a trust model.

4.4 Trust Schema Examples

We now demonstrate how the trust schema we described so far can express two different trust models. The first trust model is for our blog website framework, and the second is an example of a model that resembles trust model of DNSSEC and strictly follows the naming hierarchy to match data and key names.

4.4.1 Blog Website Framework

In the blog website example, the trust rules must capture the relationship between articles and authors, between authors and administrators, as well as between administrators and blog website configuration (blog's trust anchor). An example of the trust schema that can achieve these goals is shown in Figure 7. Note that this schema assumes that the blog's configuration key "`/a/blog/KEY/1`" is pre-authenticated (i.e., a trust anchor). Depending on the specific usage scenario, a blog reader may further authenticate the configuration key using a hierarchical trust model similar to the example in Section 4.4.2, or using some other trust model, e.g., Web-of-Trust.

The first rule in the example schema, "`article`", capture the trust constraint that authors must sign their articles with their keys. Similarly, the "`author`" rule ensures that only blog administrators can sign authors' keys. The final "`admin`" rule defines two possible relations for administrators' keys in the security framework: (1) existing administrators may delegate administrator privileges to another person; and (2) authentication paths for the administrator keys must terminate at the blog website trust anchor.

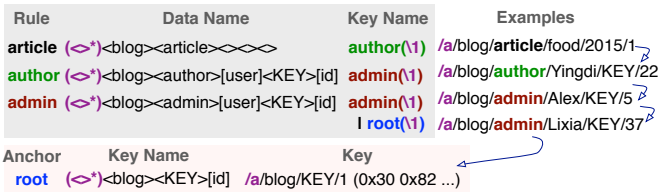

Figure 7: Trust schema the blog website framework with "`/a/KEY/1`" as the trust anchor

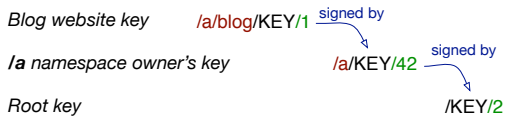

Figure 8: Example of naming in hierarchical trust model

Note that although every trust rule in the trust schema in Figure 7 uses the repeated wildcard "`<>*`" to match the website prefix, the prefix is always determined (specialized) at the moment when the "`article`" rule captures the original article data name. After the "`article`" rule captures "`/a/blog/article/food/2015/1`" data, prefix "`/a`" is propagated to the "`author`" rule as a reference to the first sub-pattern, then to the "`admin`" rule, and down to the "`root`" trust anchor.

4.4.2 Hierarchical Trust Model

In a linear hierarchical trust model, with DNSSEC [2] as a prominent example, a single rule can capture the relationship between all the data and key names; in plain English, this rule is "the signing key name must be a prefix of the data name." Because key names should be unique and need to include additional suffix components as shown on Figure 8, the trust schema for the hierarchical relationship in NDN needs to consider these additional components.[3] The overall trust in this model can be bootstrapped using one or more trust anchors associated with the top level namespace(s).

Figure 9 shows an example of the trust schema that defines the hierarchical trust relationships, consisting of a single rule and a trust anchor. The rule "`key`" captures that keys at each level of the hierarchy must be signed

[3]For simplicity, in this example we consider only authentication of public keys, but the trust model and schema can be easily extended to other data, as shown with the blog website example.

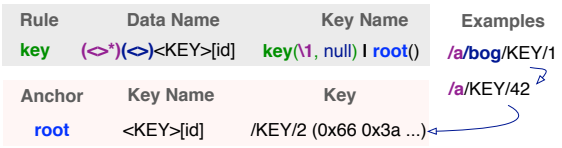

Figure 9: Trust schema for the hierarchical trust model with "`/KEY/2`" as the trust anchor

by the keys from the parent namespace, i.e., the prefix before "`KEY`" of the signing key must be one component shorter than the name of the key itself. The trust anchor ensures that the authentication path discovery terminates when it reaches the root namespace: when the prefix of the signing key before "`KEY`" is empty (just "`/`"), then it must be signed by the specified "`/KEY/2`" key.

The "`key`" rule is recursively linked to itself and to the trust anchor. In these cases, when matching data and key names, all specified patterns need to be considered, with anchor rules taking precedence. For a key "`/a/blog/KEY/1`", the rule "`key`" will extract the parent namespace of the key (i.e., "`/a`") and derive two name patterns: "`<a><KEY>[id]`" and "`<KEY><2>`". Given the signing key name matches the first pattern, the process recursively continues with the same rule, until there is a match with the trust anchor.

If the key's `KeyLocator` does not match any key name pattern, it implies that the key does not comply with the trust model and should be treated as an invalid key.

4.5 Schema for Authentication

For each data packet, the trust schema determines a valid authentication path(s) within the corresponding trust model. Given that the trust schema is expressed as formally defined rules, an *authentication interpreter* of the trust schema can automate the whole authentication process for any given trust model (Section 5.1).

For each input data packet, the authenticating interpreter finds the corresponding trust rule by matching the name of the packet against the specified name patterns in the rules. If the packet and its `KeyLocator` comply with constraints of the found trust rule, the interperter can then retrieve the public key according to the data's `KeyLocator` and recursively inspect the retrieved key according to the trust schema, until reaching a trust anchor or a pre-defined limit on the number of recursive steps. In the former case, the interpreter has collected all the intermediate public keys on a valid authentication path, thus can verify signatures starting from the trust anchor up to the input data packet. When the interpreter cannot find a rule that matches the input data packet or constructed authentication path loops or becomes overly long, the interpreter declares failure to discover the authentication path.

The input data packet is authenticated only if there is a valid authentication path according to the trust schema, and each signature on the path is verifiable and satisfies the minimum cryptographic requirements of the schema. In other words, either failure to discover authentication path or failure to verify any signature on the authentication path implies that the input data packet cannot be authenticated with the interpreted trust model.

4.6 Schema for Signing

One can also view the trust schema as a collection of constraints on a data packet's signing key, with respect to its name, signature, key type and size, etc. Thus, the trust schema also specifies the required signing process, i.e., how to select or generate signing keys given the name of the data packet. Effectively, this allows automation of the signing process using a *signing interpreter* of the trust schema (Section 5.2).

The signing interpreter takes a data packet as an input and looks up the corresponding trust rule. Instead of checking for compliance of the data's name and `KeyLocator` to the trust rule, it infers the correct name of the key that needs to be used to sign the data packet. If this key exists on the system, the interpreter will immediately sign and return the data packet. If the key does not exist, the interpreter will try to generate the key with the specified name and crypto requirements, and then sign this key by recursively re-interpreting the same schema again with the generated key as a new input. More details on how the interpeter can generate key names based on rules in the trust schema are described in Section 5.2.

Note that it is not always possible for the interpreter to automatically generate all necessary keys. If the signing process recursively reaches a trust anchor, it means that the producer does not have, or cannot create any qualifed signing key for the data packet. For example, if a not-yet authorized author is trying to sign an article for publication, the interpreter will fail to sign it, as the author does not have a valid key to sign an article, nor a key to endorse an author on the blog, nor a key to configure a new administrator in the system. Even in this case, the interpreter can still generate useful diagnostic information, e.g., which keys are missing and how to obtain them.

5. AUTOMATING TRUST

Now that we have introduced the concept of schema-based data authentication and signing, we will describe how to automate these processes, using the blog website framework as an example.

5.1 Automating Authentication

Each step of the authentication path for data (key)

packets is defined by the rules of the trust schema. Rules are linked together through a function-like invocation of rule names as part of the key name pattern definition, as shown in Figure 7. The authentication process moves forward (from one step to the next) only if the data (or key) satisfies the conditions of the rule. We can model this authentication process as a Finite State Machine (FSM), with each state representing a rule and state transitions representing function-like invocations. This way, once a data packet enters the FSM, the FSM's states define the packet's authentication path, and an automatic process can walk through these states until exiting the FSM with success or failure.

Execution of the FSM processing requires a trust schema interpreter. The interpreter used for data authentication, which we call *authenticating interpreter*, takes data packets as input, requests public keys when necessary, and outputs whether the input packet is authenticated or not. Given a trust schema for a trust model, an authenticating interpreter effectively automates the process of data authentication for this trust model. Figure 10 shows an FSM of an authenticating interpreter for the blog website trust model discussed in Section 4.4.1.

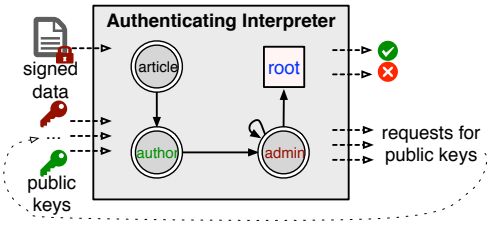

Figure 10: Finite state machine for the authentication interpreter of the blog website trust model schema

5.1.1 Authentication State

Whenever a new data packet arrives at the FSM, the interpreter determines the corresponding initial state by checking the data name against the name patterns for each state. After that, the interpreter initiates the key name checking procedure, including steps to:

- extract components from the data name according to the defined sub-patterns;
- derive the key name pattern from the rule's key name functions with the extracted components;
- check if the data's `KeyLocator` matches the derived key name pattern.

If the data packet passes the key name checking, the authentication process transitions to the downstream state of the FSM: the interpreter requests the key identified by the data's `KeyLocator` and pauses FSM processing until the key is retrieved. When the key is delivered to the interpreter, the interpreter initiates a new instance of the same checking procedure at the state on which the FSM processing previously paused. Whenever the FSM transitions to a trust anchor state, the interpreter immediately triggers verification of signatures, following the reverse path of transitions in the FSM.

5.1.2 Walking Through the State Machine

In this section we demonstrate how the authentication automation can work for the blog website trust model. We use an article data packet with name "`/a/blog/article/food/2015/1`" signed by an author key "`/a/blog/author/Yingdi/KEY/22`" as an example to show how the authentication process goes through the state machine shown in Figure 10.

Initial state.

Based on the trust schema, the article name "`/a/blog/article/food/2015/1`" will be captured by the "`article`" rule, thus the authentication process starts from the corresponding "`article`" state. When executing the key name checking procedure, the interpreter will extract "`<a>`" as the first sub-pattern and use it to derive a key name pattern through a function-like invocation of the "`author`" rule. The resulting pattern "`<a><blog><author>[user]<KEY>[id]`" will successfully match the `KeyLocator` field of the data packet and the FSM will transition to the downstream "`author`" state.

State transition.

At this point, the interpreter makes a request for "`/a/blog/author/Yingdi/KEY/22`" key and pauses processing until the key is retrieved. After retrieving the requested key, the interpreter resumes operations at the "`author`" state with the retrieved key as an input. Similarly, the interpreter extracts "`<a>`" as the first sub-pattern from the author key name and derives through the "`admin`" rule a key name pattern "`<a><blog><admin>[user]<KEY>[id]`". Assuming that the retrieved key is signed with an admin key "`/a/blog/admin/Alex/KEY/5`", the FSM will transition to the corresponding "`admin`" state.

Self-loop transition.

The "`admin`" rule in the website trust schema links to two trust rules, of which one is the "`admin`" rule itself. This self-linked rule represents a management privilege delegation from one administrator to another administrator and is represented by a self-loop transition in the FSM. This transition can capture an administrator key "`/a/blog/admin/Alex/KEY/5`" signed with another administrator key "`/a/blog/admin/Lixia/KEY/37`". In this case, the FSM transitions to the same "`admin`" state over the loopback link and the interpreter requests for the other administrator key and pauses the FSM

processing again. Note that a self-loop transition may cause an infinite loop in the authentication path, but a pre-defined limit on the number of transitions can prevent this situation. The interpreter can further optimize loop detection by recording the name of every intermediate key that each state has observed during the authentication process.

Transitioning towards the trust anchor state.

When the interpreter retrieves the public key "`/a/blog/admin/Lixia/KEY/37`", it can repeat the key name checking procedure on the "`admin`" again, deriving two patterns for key name matching: "`<a><blog><admin>[user]<KEY>[id]`" (from the "`admin`" rule) and "`<a><blog><KEY>[id]`" (from the trust anchor "`root`"). If "`/a/blog/admin/Lixia/KEY/37`" key was signed by "`/a/blog/KEY/1`" (the specified trust anchor), the second name pattern would match the `KeyLocator`. In this case, the process immediately transitions to the trust anchor state, triggering initiation of the signature verification procedure.

Signature verification.

Once the signature verification procedure is triggered, the interpreter will follow the reverse path of FSM back to the original data packet, terminating with failure if at any step it cannot verify the signature. In the example, the process will start with validating "`/a/blog/admin/Lixia/KEY/37`" key using the trust anchor key, following checking signature of "`/a/blog/admin/Alex/KEY/5`" using the validated admin key, similarly for the author key "`/a/blog/author/Yingdi/KEY/22`", terminating with checking signature of the input article data packet using validated author key.

5.2 Automating Signing

Another version of the trust schema interpreter, a *signing interpreter*, can use a trust schema to automate selection of signing keys and generation of keys when necessary. Similar to the authenticating interpreter, the signing interpreter compiles a trust schema to an FSM (Figure 11), but processes an *unsigned* data packet as input and outputs the data packet signed with a key that conforms to the trust model (or fails). During processing, the interpreter interacts with the private key store (e.g., Trusted Platform Module, TPM) to request data signing and create signing keys when they are not yet available.

5.2.1 Key Selection

Given a data packet, the signing interpreter can derive a name pattern of the key that is allowed to sign this data according to the trust model. For this purpose, it finds the state in the FSM that corresponds to the data packet, and expands the corresponding signing key name pattern. For example, let us assume that

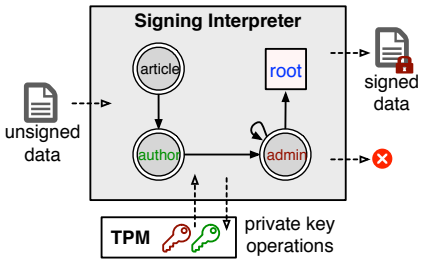

Figure 11: Signing interpreter for the blog website trust model schema

an administrator of the blog wants to publish his article "`/a/blog/article/snacks/2015/3`". This data packet will enter the FSM from the "`article`" state, at which point the interpreter can derive the key name pattern "`<a><blog><author>[user]<KEY>[id]`", as shown in step 1 in Figure 12. With the derived name pattern and the crypto requirements from the trust schema, the interpreter will search a qualified key in the TPM (step 2 in Figure 12). In our example, the admin is publishing a blog article for the first time, and is not yet authorized to do so, but the signing interpreter of the trust schema can automatically create such authorization, as we will show below.

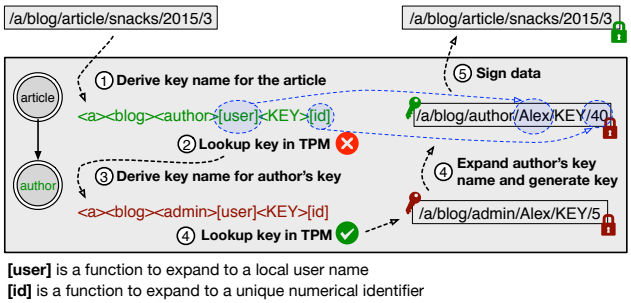

Figure 12: An interpreter processing the blog website trust schema directs the procedure of signing data "`/a/blog/article/snacks/2015/3`"

5.2.2 Creating Keys

When the interpreter cannot find a signing key that corresponds to a state of the FSM (the result of step 2 in Figure 12), it transitions to a downstream state and repeats the key searching procedure. In our example, when the interpreter realizes that there are no author keys available, it will try to find out if there are any administrator keys available. If not, the FSM will continue to transition downstream and repeat the search, until there are no more possible transitions available (note that self-loop transitions are skipped in the signing process when the signing key does not exist in the private key store). At this point the interpreter aborts the signing operation, as it will not be able to sign any-

thing that will conform to the trust model.

In our example, the signing interpreter has access to the administrator's key, and it will try to create a new author key. In order to create such key, the interpreter must derive a name for the key. In this case, the wildcard specializer `[func]` (Table 1) in a key name pattern can expand to specialize the key name. For example, `[user]` can specialize the name component for the author identifier using the local user name (e.g., "`Alex`"), and `[id]` can generate a unique identifier for the key. Therefore, at step 4 in Figure 12 (dotted blue lines), the interpreter can expand the author key pattern into "`/a/blog/author/Alex/KEY/40`". At this point, the interpreter is ready to generate an author key that satisfies the crypto requirements and overall trust model specified in the schema (step 4 on Figure 12), after which it will be ready to sign data packets of the article by this author (step 5 on Figure 12).

Note that a signing interpreter shares the same FSM as the corresponding authenticating interpreter. This feature allows a signing interpreter to "double check" the validity of selected (or generated) signing keys by authenticating these keys as an authenticating interpreter,[4] thus ensuring that the signed data can be authenticated within the same trust model.

6. DISCUSSION

6.1 Design Pattern for Security

A trust schema is more than just an approach to describe the relationships between data and key names, it is also a design pattern for NDN security. Similar to design patterns in software engineering [10], which provide general reusable solutions to commonly occurring problems in software design, the trust schema provides a reusable solution to apply commonly used trust models in NDN applications. Security experts can use trust schemas to define a set of security patterns for frequently used data authentication models. An established set of trust schemas will greatly reduce the burden on NDN application developers, who can select an appropriate security pattern for their applications during the design phase, and gain all the benefit of NDN's built-in security features. Trust schema also facilitates the automation of both packet signing and authentication, making it easy to create NDN applications with proper data authentication models, and enabling security functionality even during application prototyping.

6.2 Trust Schema Combination

Applications may combine trust schemas to achieve more powerful functionalities. Section 4 mentioned that the trust schema of a hierarchical trust model could help a consumer authenticate the trust anchor in the blog website trust schema.

In fact, a trust schema is itself a data packet, which can be signed. An operating system manufacturer may even define a meta trust schema to authenticate the trust schema of applications developed for the system, limiting software installation, execution, and access to private key stores on the operating system to only applications with authenticated trust schema. Compared to the current software distribution mechanisms (such as Apple's App Store and Google's Google Play) which only require a signature of a legitimate application developer, a *security launcher* based on the meta trust schema can provide a mechanism to limit the potential harm from unknown software installation on host operating systems.

6.3 Key Caching

In our examples, all data authentication processes walked through the complete authentication path. The process can be optimized as follows. An interpreter can cache each intermediate key of an authentication process at the state where the key is checked and verified, so that a new authentication process may find one of its intermediate keys in those states before reaching a trust anchor. In this case, the interpreter can treat the cached key as a trust anchor and immediately trigger signature verification on the reverse path, thus shortcutting the data authentication process.

6.4 Multi-path Authentication

A common concern about trust models that follow a single naming hierarchy is robustness: with only one chain of keys to the authentication target, failure to authenticate any intermediate key results in overall authentication failure. When a data packet can carry more than one signature [19], a trust model defined with a trust schema can associate names across different naming hierarchies. This capability would allow authentication of data through different chains of keys, significantly increasing the robustness of the system.

6.5 Formal Trust Schema Syntax

The syntax we used to describe the trust schema is still at an experimental stage. Trust schemas share many design philosophies with logic programming languages (such as Prolog [7]) and it may be helpful to unify the trust schema syntax with formal syntax used by existing languages.

7. RELATED WORK

[4] An optimization could be to ask a producer to maintain the chain of intermediate keys for each of its signing keys, so that the interpreter can authenticate keys immediately. In fact, it has been a common pratice to keep a complete chain of keys at the key owner side in existing authentication systems, such as TLS [9]

The focus of this paper is trust management automation. We are aware of similar efforts for Public Key Infrastructure (PKI), including a standardized path validation algorithm for X.509 certificate authentication [8], certificate chain discovery methods for SPKI certificate system [6,14], and general chain discovery mechanisms [3]. However, these studies assume a specific trust model, while automation based on trust schemas is a general trust management solution for NDN applications with different trust models. Moreover, it not only allows automation of authentication process, but also enables (at least partial) automation of the data signing process.

The designed trust schema leverages NDN naming to enforce name-based trust policies for data packets. DNSSEC [2], a security extension of DNS, adopts a similar mechanism to authenticate DNS resource records: a key bound to a DNS domain name is globally trusted to sign only DNS resource records under this domain. DANE [11] extends the name-based mechanism of DNSSEC to authenticate a TLS public keys. At the same time, both DNSSEC and DANE assume a specific hierarchical trust model, while our trust schema can capture many different trust models that NDN applications may need.

The trust schema is basically a policy language, where rules define policies on which keys are trusted to authenticate data. Compared to previous work on policy languages for access control and authorization, such as PolicyMaker [5], SD3 [12], RT [13], and Cassandra [4], our work focuses on data authentication and integrates data authentication into the NDN network architecture.

8. CONCLUSION

Usability is a fundamental requirement for any security solution. The NDN design mandates that each network-layer data packet carry a cryptographic signature for authentication, however this requirement is only on the packet format, it represents a signficant but only a first step toward securing networking applications. Our observations during the first few years of NDN application development suggest that it is a non-trivial task for application developers to properly define trust relationships between data and keys, handle proper key chain creation, and enforce authentication of data according to the defined rules. It happens too often that developers use shortcuts to get around security (e.g., hard-code keys, turn verification off "temporarily" when it blocks development progress).

In response to this important and urgent issue, we invented the idea of a trust schema to formally define application trust models. We developed prototypes of two trust schema interpreters that can convert trust schemas into finite state machines and help applications rigorously sign and authenticate data automatically. We applied our prototypes to secure a range of NDN applications, and our experience so far gives us confidence in the solution's general applicability to most, if not all, NDN applications.

We believe we have contributed a meaningful step toward a reusable approach to data authentication. We plan to apply the schematized trust management in more NDN applications and integrate the schematized trust management with operating system support. We also encourage security experts to define other commonly reusable trust schemas ("security design patterns") to faciliate data authentication in NDN applications.
